Abstract: Assessing the risk associated with earthquake is an essential component for earthquake risk mitigation. Many researchers carried out the earthquake hazard assessment of study area but earthquake risk is not carried out in Pakistan at national or provincial level. This paper presents the results of earthquake hazard and risk assessment of Khyber Pakhtunkhwa, Pakistan. Here we estimate the seismic hazard in terms of Peak Ground acceleration (PGA), using ERA framework proposed by Khan (2011) and used in risk calculation. Ambarasey's 2005 Ground Motion Prediction Equation (GMPE) is used in the hazard assessment while building inventory is developed from projected census data with minimal field sampling. Maximum PGA of 0.39 g occurs in region of district Mansehra, district Battagram and some parts of district Shangla across Indus River. It is concluded that the average risk per \$1000 ranges between (\$5 to \$145) depending upon location and class of building. Risk mitigation strategies are recommended based on the results.

Keywords: Seismic hazard, Earthquake risk, ERA, PSHA, Attenuation, seismic vulnerability, Earthquake, KPK, Risk mitigation

1. Introduction

Kashmir(2005) and Baluchistan(2013) earthquakes in region highlighted the need of seismic hazard and risk assessment at national level. Few studies have been carried out on hazard assessment of selected parts of the Khyber Pakhtunkhwa Province (Ali Q, 2005; Monalisa et al., 2007; PMD-NORSAR, 2007; Ahmed, 2008; Khan, 2011). But no broad scale study is done so far on Earthquake Risk Assessment (ERA) in Pakistan on national or provincial level. Therefore, the ERA of the Khyber Pakhtunkhwa province is selected. KPK is located in the north-west of Pakistan (Shown in Figure 1). The capital of KPK province is Peshawar. The province consists of 24 districts with approximate estimated total population over 25 million (FBS Pakistan, 2012). Hindukush and Some portion of Himalayas range are in KPK which make it seismically active region. Kashmir 2005 earthquake that claimed the lives of more than 86,000 people and a devastation of financial loss of approximately \$3.5 billion (ADB-WB, 2005) severely affected some areas of KPK province. Approximately 3.5 million people became homeless, bereaving them of food and shelter (ERRA, 2007)

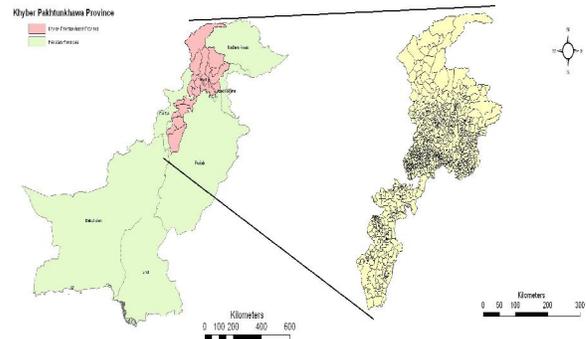

Figure 1. Study Area –Khyber Pakhtunkhwa (KPK) Province Pakistan

Earthquake Risk Assessment of unreinforced brick masonry(URBM) structures for Mansehra was carried out by Naveed (2011). For 475 year return period a PGA of 0.25g on soil site estimated by Naveed (2011). He reported that 5% of the total single storey URBM buildings will collapse, 20% of the buildings will attain heavy damages and 21% buildings will be in repairable damages. Only 54% of the buildings will have no damage and estimated total loss of about US\$ 7.64 million. Total injuries of 2294 ±459 people and fatalities of 29±6 will be expected for the exposure of 50 years.

Framework developed by Khan (2010) is used in this study for hazard and risk assessment of KPK province. This framework is suitable for developing

countries where detailed data on seismo-tectonic, vulnerability and building inventory are not readily available.

2. Seismo-tectonic & Seismicity

Pakistan is situated on the western-fractured edge of the Indo-Pakistan sub-continental plate and lies on the northwestern corner of the Indian lithospheric plate, the southern part of the Afghan craton, and the northern part of the Arabian oceanic subducting plate (Zaigham and Mallick, 2000). The Indian subcontinent has been impacting with Eurasian sub continent in the course of last 30-40 million years (Aitchinson et al., 2007). Throughout this period continental lithosphere longer than 2000 km has abbreviated to huge mountain ranges. Northern, Western and Southern Pakistan, Kashmir and Northern India and Afghanistan are along zones of high seismic movement. Earthquakes happen along an extremely active thrust fault framework in the locale.

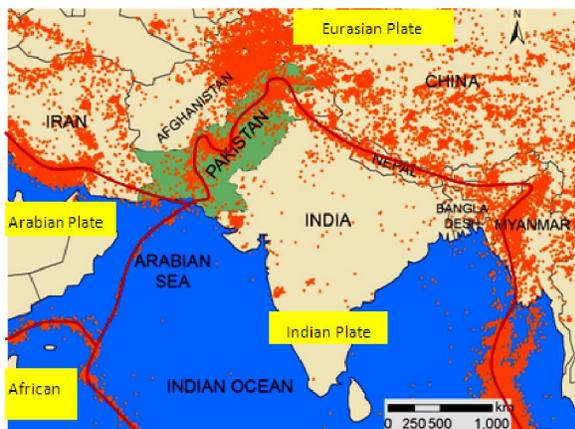

Figure 2. Seismic activity around the Indian plate boundaries between 1973 and 2010 (after Khan, 2011).

Earthquakes along active faults in Pakistan and adjacent faults in India and Afghanistan are the direct result of the Indian sub-continent moving northward and colliding with the Eurasian continent at a rate of about 5cm/year (Sitharam et al., 2013). Before this collision, this plate was moving with the highest rate of 20cm/year (Kumar et al., 2007). This major tectonic impact is initiating elevate that prepares the most noteworthy mountain tops on the planet incorporating the Himalayan, the Karakoram, the Pamir and the Hindu Kush ranges. Figure 3 shows the seismic events around the Indian plate verges between 1973 and 2010.

The major tectonic features of Pakistan and surrounding areas are shown in Figure 3 are based on the information provided by Building Code of

Pakistan (Khan, 2011). The major fault zones in Pakistan include the Sulaiman stretch in transpression and the Himalayan zone under-thrusting the Eurasian plate (Jadoon, 1992).

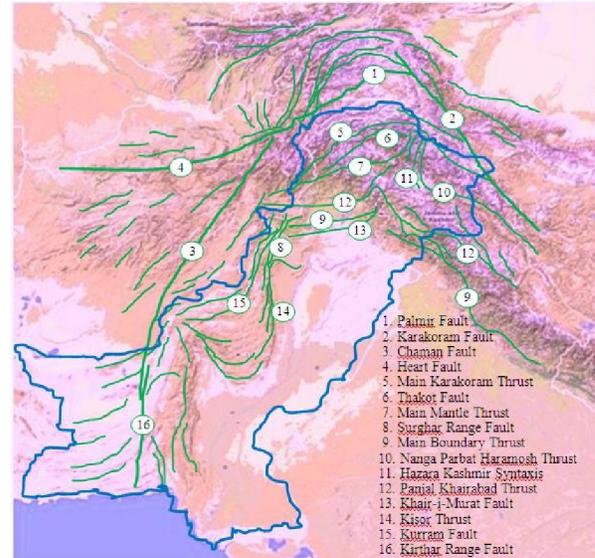

Figure 3. Major tectonic features in Pakistan. (after Khan,2011)

3. Earthquake Catalogues & Seismic Zones

Historical and Instrumental earthquake record are collected from different sources. Historical earthquake records are compiled by Oldham, 1893, Heukroth and Karim, 1970, Ambraseys et al. 1975 and Quittmeyer and Jacob, 1979. As the historical catalogues only contain large magnitude event so these catalogues are incomplete. However historical events plays important role in SHA as these events leads us to the location of seismic source.

Instrument earthquake records are taken for International Seismological Center (ISC, 2012).100 years instrumental records are use in hazard and risk calculation.

Seismic zones sets by PMD-NORSAR (2007) including the study area and surrounding regions shown in figure (4a) are used in this study. This division of seismic source zones is dependent upon seismicity, geology and source mechanism.

Seismicity is shown in Figure (4b) it is observed that seismic occasions are bunched in north regions zones 5, 6, 7, 14 & Zone 15 in Hindukhush and zone 1 Himalayans. In south regions the Zone 3 and zone 4 show very high seismicity.

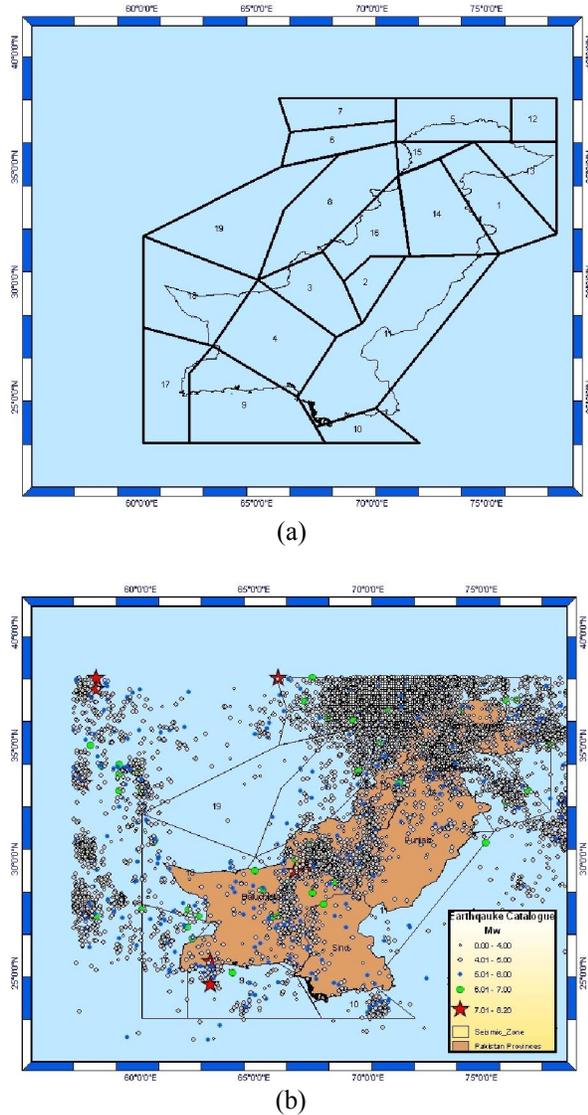

Figure 4. (a). Seismic zones, (b) spatial representation of instrumental seismicity.

4. Methodology

Khan (2010) developed ERA framework which required minimal data and easy to use for hazard and risk assessment. This Framework is modified to carry out the ERA of KPK. The key risk factors for this purpose consist of historical and instrumental earthquake records, seismic zones, Selection of Suitable vulnerability Curves and development of building inventory for building stock in study area. Historical and instrumental earthquake records and seismic zones are discussed in previous section. In first step hazard assessment is carried out using this modified data and then results are used in risk calculation combining the PGA(g) with known vulnerability of buildings in study area. The details of building classes, their vulnerability curves and

development of building inventory is explained in following section.

5. Selection of seismic vulnerability relationships and development of Building Inventory

Seismic vulnerability is expressed as Mean Damage Ratio (MDR), which the ratio of cost of damage item to the replacement cost of same item. Vulnerability is relationship between MDR and earthquake intensity. Vulnerability assessment can be done using empirical method and analytical method. In many developing countries like Pakistan there is no previous vulnerability assessment done on the building stock. Many researchers in Pakistan are currently working on development of vulnerability relationship of different building classes Rafi (2012) has recently developed fragility curve for Adobe building. Sohaib (2011) developed vulnerability curve for existing reinforced concrete frames using empirical and analytical techniques. The vulnerability relationship for all different building classes in not yet developed. Due to this reason vulnerability curve for similar type of region will be used.

Development of building inventories by any method requires extensive computation and time. Very simple approach to this problem is use of census data. In this study projected census data i.e. census 1998 (FBS, 2012) is used with field verification. Buildings in the study area are classified into the following categories.

1. Reinforced Concrete Frames (RCF)
2. Reinforced Concrete Frame with infill masonry (RCI)
3. Un-reinforced Masonry (URM)
4. Rubble Stone Masonry (RSM)
5. Dhajji Structures (DJ)
6. Adobe Structures (AD)

5.1 Reinforced Concrete Frame (RCF)

Reinforced concrete frame exist as commercial units in the urban area and their height may varies from 5 to 10 stories. Large numbers of these building are 3-6 stories. These buildings performed poorly in the Kashmir (2005) Earthquake due to lack of seismic design, soft storey, poor detailing and poor quality of materials.

5.2 Reinforced Concrete Frame with infill masonry (RCI)

Building Stock in the study area contains large number of this type building. These building consist of 3-6 storeys. Reinforce concrete framed with infill masonry is common building type for residential and commercial building in urban areas in study region. Most of buildings are non-engineered and more vulnerable than the RCF due to lack of detailing, poor quality of construction and materials.

Performance of these building remained very poor in Kashmir (2005) Earthquake.

5.3 Un-Reinforced Masonry (URM)

This the most common type of residential building throughout the Pakistan as well as in the study region. Brick masonry with Cement-sand Mortar (CSM) is used for this type of building. These building are 1 to 3 storeys with RCC roofing and equally used for residential and commercial purposes. This type of building performed better than RCI and RCF in Kashmir (2005) earthquake.

5.4 Rubble Stone Masonry (RSM)

Dry Rubble or Rubble stone building not only exists in certain rural areas but the construction of these building is still in use. People used locally available stone without dressing for the construction of houses. This type of building is highly vulnerable to earthquake and has shown very poor performance in Kashmir (2005) earthquake (Ahmed, 2012).

5.5 Dhajji Structures (DS)

This structure is mainly located in Northern areas of Pakistan and Kashmir. These are wooden framed with different bracing pattern, the spaces between braces is filled with mud masonry or dry stone. In India and Pakistan this is also known as Dhajji Dewari. Indian Standard Codes referred this type of construction as brick noggged timber frame construction (WHE, 2012). Similar type of construction in Turkey and United Kingdom called as "Himis" and "Fachwerk" respectively. These structures performed very well in Kashmir (2005) earthquake and in rehabilitation phase Earthquake Reconstruction and Rehabilitation Authority (ERRA) recommended to use these structures and more than 100 thousands housed are built using this technique in KPK and Kashmir. The typical examples of Dhajji Structures are shown in Figure (5a) and 5(b).

Figure 5(a) Dhajji Structures with mud masonry infill in Union Council Pashto, Battagram

Figure 5(b) Dhajji Structures with dry stone infill in Union Council Pattan Kalan, Abbottbad.

5.6 Adobe Structures or Mud wall Structures (AD)

This is non-engineered and low cost building. These are mud wall structure or mud brick with mud mortar to bind these brick. This type of building exists in rural area of Pakistan. In KPK these type of building exist in rural area of Abbottabad, Mansehra, Battagram, Shangla, Kohistan, Peshawar, Nowshera, Bannu, Lakki Marwat, Kohat etc. This type of building is highly vulnerable.

In this study vulnerability curves developed by GESI (2002) are used for calculation of damage. Vulnerability curves for above mentioned building classes is shown in figure 5.

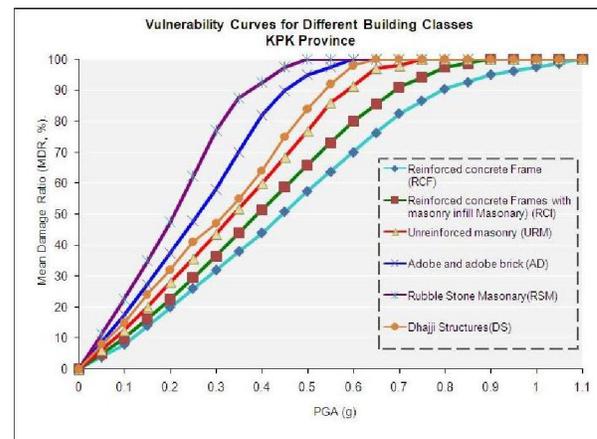

Figure 5. Vulnerability curves for Building stock of KPK

Building density for study region is shown in the Figure 6. It is observed that the building density in rural areas is low and ranges from 0-25 buildings/Km². whereas building units in some of urban areas is very high.

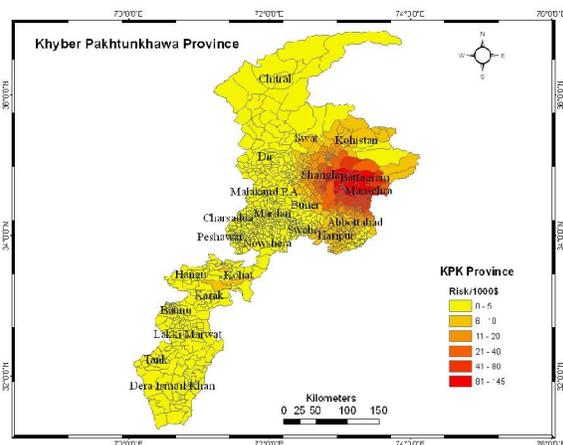

Figure 10. Risk Map of Study region in 100 years (Risk per \$1000)

In figure.10 Risk per \$1000 is spatially presented. It is observed that monetary risk is high in Mansehra, Battagram and Shangla districts because of high vulnerability of clustered or densely placed building stocks coupled with high earthquake hazard.

7. Conclusion

This paper presents the result of hazard and risk calculated using ERA framework developed by Khan (2010). The Seismic hazard map for 100 years is developed. Maximum PGA is 0.39g for some part of Mansehra, Battagram and District Shangla. Twenty UCs of district Mansehra and district Battagram each and five UCs of Shangla are at Maximum hazard.

Result indicates that seismic risk is concentrated in following six districts in order of severity i.e Masehra, Battagram, Kohistan, Swat, Chitral and Abbottabad due to high hazard and vulnerability of building stock. It is concluded that average risk per \$1000 ranges between \$(5 -145) depending upon the type of building and its location.

8. Recommendations for Risk Mitigation

a) According to risk map Union Council of Mansehra, Battagram and Shangla are at high risk, earthquake resistant construction with quality control is recommended for mentioned for these areas.

b) Seismic retrofitting is recommended for buildings in Mansehra, Battagram, Shangla Swat Abbottabad, and Chitral district.

c) Since Rubble stone masonry is the major contributor of collapsed building therefore, construction of these building should be prevented in high seismic zones.
